

# Trichomycetes (Zygomycota) in the Digestive Tract of Arthropods in Amazonas, Brazil

Yamile B Alencar/<sup>+</sup>, Claudia M Ríos-Velásquez\*, Robert W Lichtwardt\*\*, Neusa Hamada

Coordenação de Pesquisas em Entomologia, Instituto Nacional de Pesquisas da Amazônia, Caixa Postal 478, 69011-970 Manaus, AM, Brasil \*\*Department of Ecology & Evolutionary Biology, University of Kansas, Lawrence, KS, US \*Centro de Pesquisas Leônidas e Maria Deane-Fiocruz, Manaus, AM, Brasil

*Eight species of Harpellales and three species of Eccrinales (Zygomycota: Trichomycetes) were found associated with the digestive tract of arthropods from terrestrial and aquatic environments in the central Amazon region of Brazil. New species of Harpellales include: Harpella amazonica, Smittium brasiliense, Genistellospora tropicalis in Simuliidae larvae and Stachylinea paucispora in Chironomidae larvae. Axenic cultures of S. brasiliense were obtained. Probable new species of Enterobryus (Eccrinales), Harpella, and Stachylinea (Harpellales) are described but not named. Also reported are the previously known species of Eccrinales, Passalomyces compressus and Leidyomyces attenuatus in adult Coleoptera (Passalidae), and Smittium culisetae and Smittium aciculare (Harpellales) in Culicidae and Simuliidae larvae, respectively. Comments on the distribution of some of these fungi and their hosts in the Neotropics are provided.*

Key words: Coleoptera - Diplopoda - Diptera - fungi - Trichomycetes

Trichomycetes (Zygomycota) are obligate symbionts that live in the digestive tract of various insects and other arthropods, attached without penetration to the linings of the gut (Lichtwardt 1986). The large variety of hosts includes terrestrial, marine and freshwater arthropods, most commonly Chironomidae, Culicidae, Simuliidae, Coleoptera, Plecoptera, and Ephemeroptera, as well as several kinds of Crustacea and Diplopoda (White et al. 2000).

The relationship of Trichomycetes to their hosts is generally commensalistic or pathogenic, and, in some cases, mutualistic depending on developmental and environmental conditions (López Lastra 1990, Lichtwardt 1996).

The class Trichomycetes consists of three orders: Harpellales, Asellariales, and Eccrinales, of which only Harpellales contain culturable species (Misra & Lichtwardt 2000). Other authors have included a fourth order: Amoebidiales. Though protozoans (Benny & O'Donnell 2000) and therefore not phylogenetically related to fungi, Amoebidiales have been traditionally included in the Trichomycetes (Lichtwardt 1986, 1996) because of their ecological similarities.

Little is known about Trichomycetes in South America (López Lastra 1990, Lichtwardt & Arenas 1996, Misra 1998, Lichtwardt et al. 1999a, 2000), whereas they have been much better studied in the Nearctic (Lichtwardt 1986, Labeyrie et al. 1996, Lichtwardt et al. 2001).

In this investigation we present a taxonomic study and information about the biogeography of Trichomycete fungi in the central Amazon. The taxonomic part includes descriptions of new species of Harpellales: *Harpella amazonica*, *Smittium brasiliense*, *Genistellospora tropicalis*, and *Stachylinea paucispora*. Other species of *Harpella*, *Stachylinea*, and *Enterobryus* (Eccrinales) are described but not named due to insufficient number of collected specimens. We also record previously known species, including *Smittium culisetae* Lichtwardt in mosquito larvae (Pereira et al. 2000), *Smittium aciculare* Lichtwardt in Simuliidae larvae, *Passalomyces compressus* (Thaxter) Lichtwardt, White, Cafaro & Misra (1999b) and *Leidyomyces attenuatus* (Leidy) Lichtwardt, White, Cafaro & Misra (1999b) in adult Coleoptera (Passalidae).

## MATERIALS AND METHODS

This study was conducted in October 2000 in different localities within the municipalities of Manaus and Presidente Figueiredo, Amazonas (Fig. 1, Table).

Larvae of aquatic insects (Chironomidae, Culicidae, Simuliidae) were collected using forceps, pipettes, sieves, and nets, placed in containers and stored under refrigeration before being dissected in the laboratory. Coleoptera (Passalidae) and Diplopoda were dug from decomposing tree trunks or from ground litter. In the laboratory, the arthropods were dissected in distilled water with forceps and needles. The peritrophic membrane and hindgut were mounted on microscope slides in distilled water for detection of the presence of gut fungi. Measurements of fungal structures (thalli, holdfasts, spores) were done from slides of living material examined with phase-contrast microscopy and selectively photographed. The fungi were preserved on semi-permanent slides in lactophenol-cotton blue and sealed with colorless fingernail polish.

Cultures were made according to methods described by Lichtwardt (1986). Hindguts with Harpellales were

This study received partial financial support from PPI 1-3070, 1-3630, and CNPq (AP-400028/99-9).

washed in a penicillin-streptomycin antibiotic solution and plated on dilute brain-heart infusion agar (1/10 BHI) with a thin overlayer of distilled water. Successful isolates were transferred to slants of the same medium to which about 1 ml of distilled water had been added.

Type specimens of new species consist of prepared slides or photographs, and are deposited in the Herbário do Instituto Nacional de Pesquisas da Amazônia (Inpa), Manaus, AM, Brazil.

#### DESCRIPTION OF NEW SPECIES

*Genistellospora tropicalis*, sp. nov

Ríos-Velásquez, Alencar, Lichtwardt & Hamada

(Figs 2-6)

Branched thalli with a main axis 114-243  $\mu\text{m}$  long from which lateral branches arise. Holdfast may be shaped like a horseshoe. Ovoid trichospores [20-27 x 3-(6)-8  $\mu\text{m}$ ] without collar, each with about 6 fine appendages, produced in high numbers. Zygospores (50-60 x 8-10  $\mu\text{m}$ ) attached medially and oriented parallel to the axis of the zygosporophore. Zygosporophores about 40-45 x 7-8  $\mu\text{m}$ . Supporting cell (below zygosporophore) with a straight or thumblike lateral extension. Frequently found in Simuliidae larvae and sometimes observed together with *Harpella* and *Smittium* in the same simuliid gut.

*Diagnosis*: thalli ramosi, axe primario 114-243  $\mu\text{m}$  longo ex eo rami laterales orientes. Haustoria interdum hippocrepica. Trichosporae ovoideae [20-27 x 3-(6)-8  $\mu\text{m}$ ], collare carentes, abundantes. Zygosporae (50-60 x 8-10  $\mu\text{m}$ ), medifixae, paralleliter ad axem zygothori dispositae. Zygosporophora ca. 40-45 x 7-8  $\mu\text{m}$ , cellula suffulta eorum extensione laterali polliciformi recta vel flexa praedita. In

Fig. 2: *Genistellospora tropicalis*. Entire thallus removed from a Simuliidae larva hindgut bearing trichospores and one zygospore (arrow). Scale bar = 25  $\mu$ m

proctodae larvarum Simuliidarum

*Etymology*: from the tropics

*Holotype*: microscope slide BR-8-1, from which photographs B19 and B20 were made (show thallus with attached trichospores, released trichospores and zygospores) prepared from a larva of *Simulium goeldii* Cerqueira & Nunes de Mello (Diptera: Simuliidae) collected on 6-X-2000 from Igarapé I (Site 1, Table).

*Paratype*: *Simulium ulyssesi* (Py-Daniel & Coscarón), *S. goeldii* and *Simulium trombetense* Hamada, Py-Daniel & Adler larvae infected with *G. tropicalis* were found in streams at the Sites 2 and 8 (Table). Almost all specimens examined were infected with *G. tropicalis*, most of them with trichospores and a few with zygospores.

Four other species of *Genistellospora* are currently described: *G. homothallica* Lichtwardt 1972, *G. nubila* Lichtwardt 1997, *G. guanacastensis* Lichtwardt 1997 and *G. tepidaria* Lichtwardt 1997. *G. homothallica* appears to have a worldwide distribution, being found in US, England (Lichtwardt 1986), Chile (Lichtwardt & Arenas 1996), Costa Rica (Lichtwardt 1997) and Argentina (Lichtwardt et al. 1999a). The other three species have only been found in Costa Rica (Lichtwardt 1997). Of the previously described species, *G. tepidaria* is the most similar to *G. tropicalis*, whose trichospores (21-31 x 9-11  $\mu$ m) are wider and zygospores (58-70 x 10-15  $\mu$ m) are slightly longer and wider than those of *G. tepidaria*.

*Harpella amazonica*, sp.nov.

Ríos-Velásquez, Lichtwardt, Hamada & Alencar  
(Figs 7-9)

Narrow and short thalli, about 104-150  $\mu$ m long by 3-4  $\mu$ m diam. Base rounded with holdfast of less diameter than the thallus. Curved to almost coiled trichospores (33-52 x 3-4  $\mu$ m), with about 4 very fine appendages. Thalli producing very few trichospores (only 2 to 3 per thallus). Zygospores unknown. Attached to the peritrophic membrane of Simuliidae larvae (black fly).

*Diagnosis*: thalli angusti brevesque, ca. 104-150  $\mu$ m longi, 3-4  $\mu$ m diam., ad basem rotundati, haustoriis in diametro quam thallis minoribus. Trichosporae (33-52 x 3-4  $\mu$ m), curvae vel subspirales, 2-3 per thallum. Zygosporae ignotae. Ad membranam peritrophicam larvarum Simuliidarum affixi.

*Etymology*: from the Amazonian region.

*Holotype*: microscope slide BR-7-1, from which photographs A3, A4 and A5 were made (show thallus, holdfast and attached and released trichospores) prepared from a larva of *Simulium rorotaense* Floch & Abonnenc (Diptera: Simuliidae) collected on 11-X-2000 from Igarapé da Onça (Site 9, Table).

*Paratype*: *S. goeldii* larvae infected with *H. amazonica* were found in streams at the Sites 1 and 2 (Table). Almost all specimens examined were infected with *H. amazonica*, but few showed trichospores.

Four other species of *Harpella* are currently described: *H. melusinae* L. Léger & Duboscq, 1929 found in many regions of the world (Australia, New Zealand, Japan, North America, Europe and many regions at Northern Hemisphere); *H. leptosa* Moss & Lichtwardt, 1980 known only from northwest Montana and Utah, US; *H. meridionalis* Lichtwardt & Arenas, 1996 found in Chile and Argentina and *H. tica* Lichtwardt, 1997 found in Costa Rica (Lichtwardt 1997), Puerto Rico (White et al. 2000), and Argentina (Lichtwardt et al. 2000).

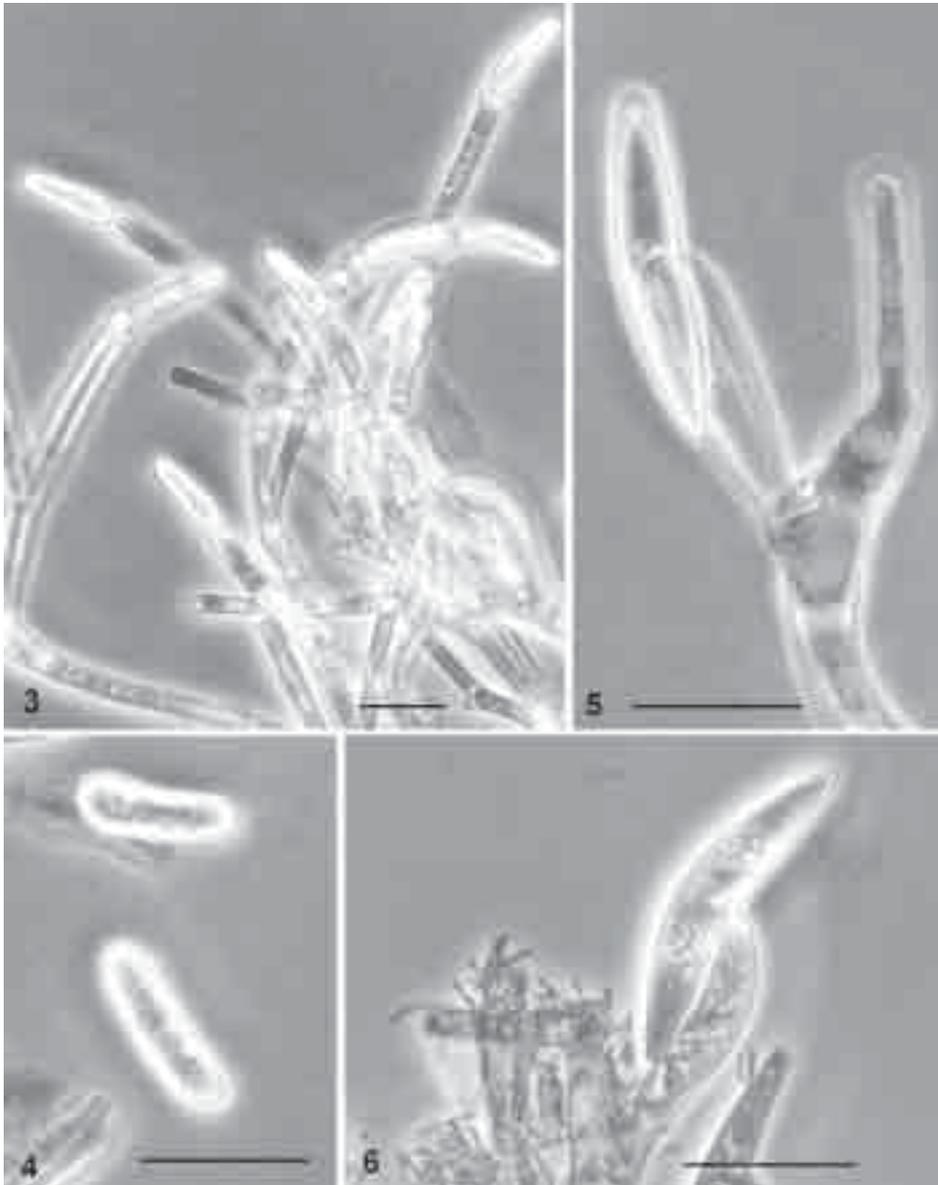

*H. amazonica* has a shape similar to *H. melusinae*, *H. leptosa* and *H. meridionalis* being close to *H. meridionalis*, but thalli and trichospores of *H. amazonica* are shorter and narrower. Trichospores are different from those of *H. tica*, which are sigmoid.

*Smittium brasiliense*, sp. nov.

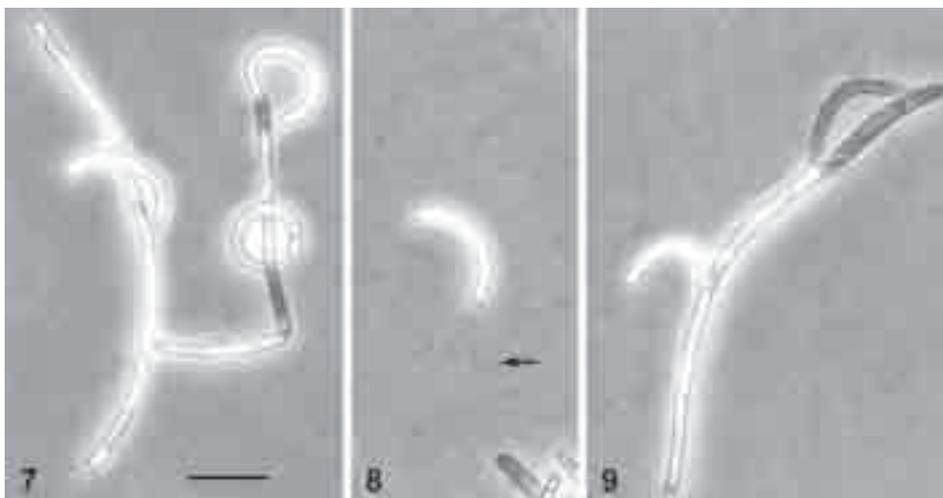

Alencar, Lichtwardt, Ríos-Velásquez & Hamada  
(Figs 10-21)

Mature thalli often growing in large tufts or clumps, verticillate branching. Holdfast horseshoe shaped. Long-ellipsoidal trichospores (13-)18(-26) x 1.6(-3)  $\mu$ m with a very short collar and one appendage. Biconical zygospores almost cylindrical (32-)40(-43) x 4-5  $\mu$ m with a collar near one end and a single appendage. In the hindgut of Simuliidae (black fly) larvae.

*Diagnosis*: thalli maturi saepe in fasciculos vel caespites magnos crescentes, in verticillis ramificantes. Haustoria hippocrepica. Trichosporae longi-ellipsoideae, (13)18(-26) x 1.6(-3)  $\mu$ m, collare brevissimo atque appendiculo unico praeditae. Zygosporae biconicae, subcylindrica, (32)40(-43) x 4-5  $\mu$ m, collare prope extremum alterum atque appendiculo unico praeditae. In proctodaeo larvarum Simuliidarum.

Figs 3-6: *Genistellospora tropicalis*. Fig. 3: attached trichospores. Fig. 4: detached trichospores. Figs 5, 6: zygospores. Scale bars = 25  $\mu$ m

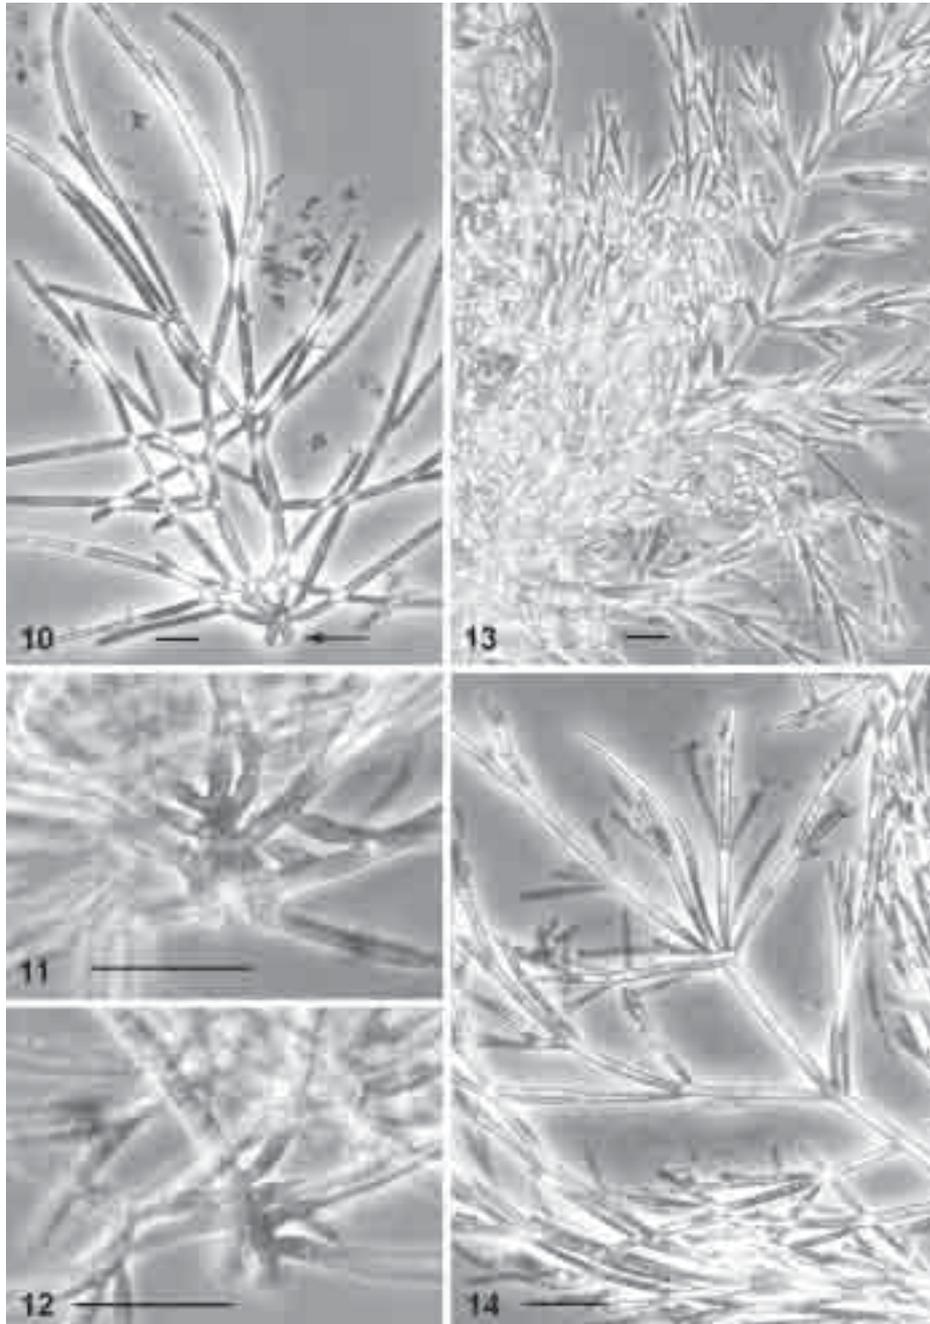

Figs 7-9: sporulating thalli of *Harpella amazonica* inside the peritrophic membrane of a Simuliidae larva, and one detached trichospore with multiple barely visible appendages (arrow pointing to one). Scale bar = 25  $\mu$ m for all figures

*Etymology*: from Brazil.

*Holotype*: microscope slide BR-6-1, from which photographs A00 and A1, were made (show branched thalli, holdfast horseshoe shaped, released and attached trichospores and zygospores) prepared from a larva of *S. goeldii* (Diptera: Simuliidae) collected on 10-X-2000 from Igarapé Barro Branco (Site 2, Table).

*Paratype*: *Simulium ulyssei*, *S. goeldii* and *S. rorotaense* larvae infected with *S. brasiliense* were found in streams at the Sites 1 and 10, Table. *S. brasiliense* was very common in the examined specimens.

From the species of *Smittium* currently described, *S. brasiliense* trichospores and the shape of zygospores most closely resemble those of *Smittium dipterorum* Lichtwardt, 1997, a species found within the hindgut of Simuliidae and Chironomidae larvae in Costa Rica (Lichtwardt 1997). However, in *S. dipterorum* zygospores are longer than in *S. brasiliense*. Another significant difference is the presence of a horseshoe shaped holdfast structure in *S. brasiliense*, whereas *S. dipterorum*'s attachment to the cuticle is by a simple secreted structure. In the Amazonas region, *S. brasiliense* was observed

Figs 10-14: *Smittium brasiliense* from a Simuliidae larvae. Fig. 10: immature thallus with horseshoe-shaped basal cell (arrow) by which the thallus was attached to the hindgut cuticle. Figs 11, 12: basal cells of mature thalli. Fig 13: part of a dense thallus removed from a hindgut. Fig 14: verticillate branching typical of this species. Scale bars = 25  $\mu$ m

sharing the same Simuliidae gut with *Harpella* and *Genistellospora*.

*Stachylina paucispora*, sp. nov. Lichtwardt  
(Figs 22-23)

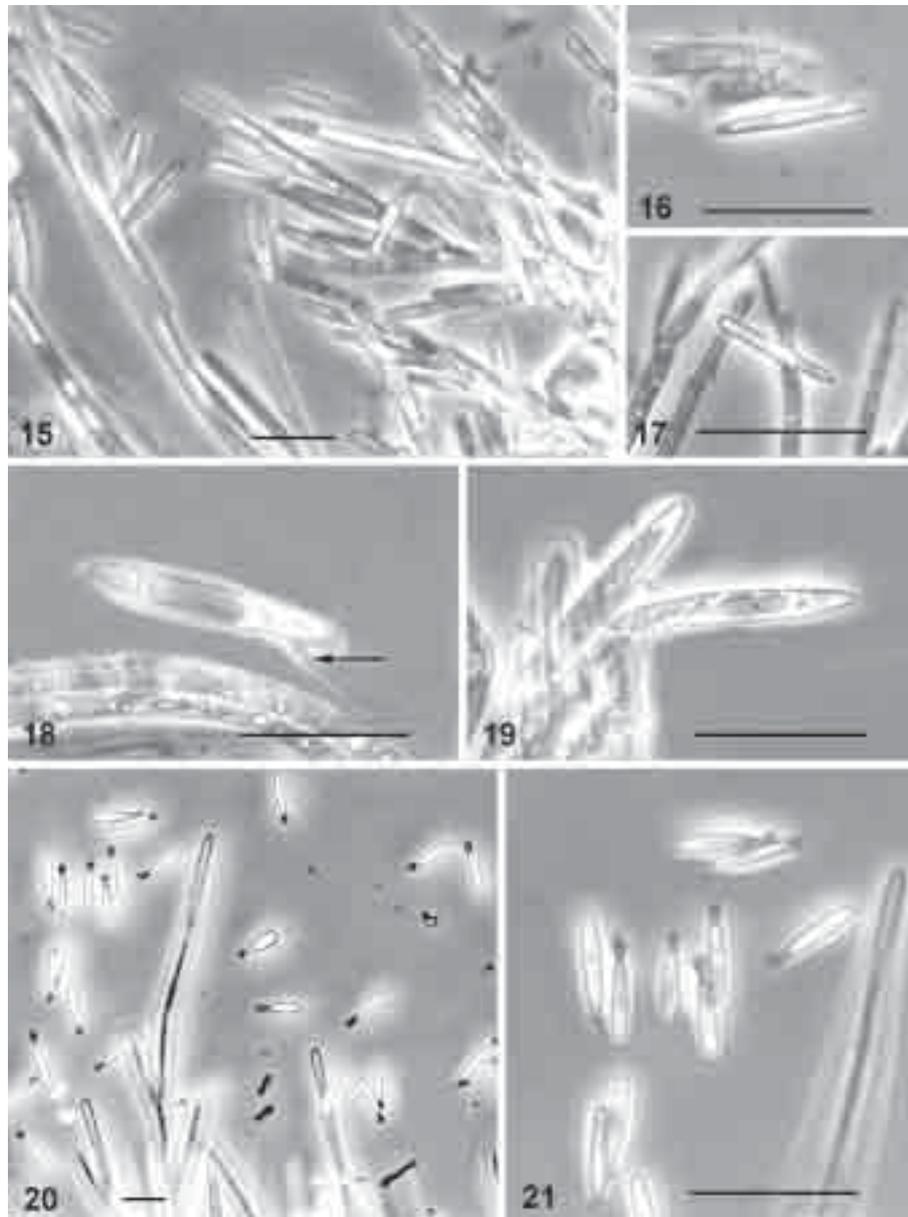

Thallus fusiform ~70-85 x 6-7 µm. Long-ellipsoidal trichospores, 29-40 x 6-8 µm with a single appendage and without a collar. Two of the thalli are conjugating (this is very uncommon in *Stachylina*). One to two trichospores per thallus. In the hindgut of Orthoclaadiinae.

*Diagnosis:* thali fusiformes, ~70-85 x 6-7 µm. Trichosporae longi-ellipsoideae, 29-40 x 6-8 µm, 1-2 per thallium. In

proctodaeo larvarum Orthoclaadiinarum (Chironomidarum). *Etymology:* Latin paucus = few, for the few spores produced per thallus.

*Holotype:* microscope slide BR-9-1, from which photographs B11-B12 were made (show thalli and trichospores) prepared from a larva of (Orthoclaadiinae, *Cricotopus*) (Diptera: Chironomidae) collected on 10-X-2000 from a concrete ditch with running water near Paiol da Cultura, Inpa (Site 5, Table). This larva also had a nonsporulating *Smittium* in its hindgut.

Two of the thalli appeared to be conjugating (Figs 22, 23), which is very uncommon in *Stachylina*.

Figs 15-21: *Smittium brasiliense*. Fig. 15: sporulating branchlets. Figs 16, 17: released trichospores. Figs 18, 19: zygospores, one showing a single appendage (arrow) trailing from a small collar. Figs 20, 21: trichospores produced by thalli in an axenic culture of the fungus. Scale bars = 25 µm

**SPECIES WITH PUBLISHED NAMES**

*Leidyomyces attenuatus* (Leidy) Lichtwardt, White, Cafaro & Misra, 1999 (Figs 22-23)

*Leidyomyces attenuatus* (Eccrinales) is found virtually throughout the range of Passalidae (Coleoptera) in the Americas (Lichtwardt et al. 1999b). The fungus was named by Leidy (1849b) as *Enterobryus attenuatus*, which he discovered in passalid beetles in Eastern United States. A more complete description of the fungus was provided by Lichtwardt (1957) under Leidy's original name. Subsequently, what appears to be the same morphological species, now renamed *L. attenuatus*, has been found in some Caribbean islands, Central America, and South America as far south as São Paulo, Brazil. The original collections in Brazil included four regions of the Amazon, one of which was Manaus (Lichtwardt et al. 1999b).

Thalli of *L. attenuatus* occur in the anterior part of the long passalid hindgut. The most anterior thalli commonly are grouped into clusters of unbranched thalli whose individual holdfasts are fused into one holdfast complex (Mayfield & Lichtwardt 1980). This feature is illustrated on the web site. The range of hosts includes many genera and species of Passalidae. The fact that it has such a wide host range and geographic distribution suggests that *L. attenuatus* evolved in Passalidae at the time of their early

radiations. In the Reserva Ducke (Site 1) we collected on 6-X-2000 several specimens of the large beetle, *Passalus convexus* Dalman, 1814, from partially rotted logs. Their guts contained both *L. attenuatus* and a second hindgut fungus, *Passalomyces compressus*, described below.

*Passalomyces compressus* (Thaxter) Lichtwardt, White, Cafaro & Misra, 1999 (Figs 24, 25)

This unusual Eccrinales in Passalidae hindguts has been found only in tropical regions of the Americas. First named *Enterobryus compressus* by Thaxter (1920) from a passalid species collected in the Dominican Republic, it has now been found in Costa Rica, Panama, and Brazil (Macapá and Belém) and was renamed by Lichtwardt et al. (1999b). The unbranched thalli at maturity can project from the anus, and some are actually attached to the beetle's anal plates. Sporangiospores are flattened and allantoid in shape, and emerge from the side of the sporangium. Specimens of *P. compressus* came from the same passalid collection as *L. attenuatus*, above.

*Smittium aciculare* Lichtwardt, 1990 (Figs 26-28)

*Smittium aciculare* was described in Lichtwardt and Williams (1990) from collections of *Austrosimulium mirabile* Mackeras & Mackeras and *Simulium clathrinum*

Figs 22, 23: *Stachylina paucispora* from a Chironomidae larva. Mature thalli within the peritrophic membrane, each producing one or two trichospores. Two sporulating thalli that appear to be conjugating; the arrow points to an appendage within the generative cell. Scale bars = 25 µm

Mackerras & Mackerras (Simuliidae) in tropical Queensland, Australia. In Amazonas, we found what appears to be the same species in larvae of *Simulium trombetense* at Sites 7 and 8 collected 11-X-2000. The original description of this Harpellales stated that thalli were 150–350  $\mu\text{m}$  long, acicular, sparsely branched or unbranched, and tapered at the base,

Figs 24, 25: sporulating tips of unbranched thalli of *Passalomyces compressus* (Eccrinales) that were projecting from the anus of a Passalidae beetle, consisting of flattened sporangia each bearing one sporangiospore. Scale bars = 25  $\mu\text{m}$

with long fusiform-ellipsoidal trichospores 28–30  $\times$  3.4  $\mu\text{m}$ . Our specimens had thalli that were unbranched, about 200  $\mu\text{m}$  long, and tapered at the base (Fig. 26), with trichospores  $\sim$ 30–33  $\times$  3–3.5  $\mu\text{m}$ , with a very short collar. Though the two sites are very disjunct, the fungi appear to be conspecific.

*Smittium culisetae* Lichtwardt, 1964  
(Figs 29–32)

*Smittium culisetae* appears to have a worldwide distribution. It has been reported from Japan, Australia, New Zealand, Hawaii, continental US, France, Argentina, Costa Rica, and Brazil (Lichtwardt 1986, 1997, Lichtwardt et al. 1999a, Pereira et al. 2000). The most common host is mosquito larvae (Culicidae), but this Harpellales has an unusually wide host range that includes Simuliidae, Chironomidae, Ceratopogonidae and Tipulidae; in Australia it was once found in Ephemeroptera nymphs (Lichtwardt & Williams 1990). The species is easily identified by its relatively small trichospores [(11)16(–30)  $\times$  (3–)4(–7)  $\mu\text{m}$ ] with a slight bulge below the middle (Figs 31, 32) and a very short collar, and thalli with verticillate branching.

Cultures of *S. culisetae* from Amazonas were isolated from *Culex* sp. (Culicidae) larvae collected on 5-X-2000 at Centro Ecológico (Site 4).

**SPECIES ILLUSTRATED AND DESCRIBED,  
BUT NOT NAMED**

*Enterobryus* sp.  
(Figs 33–35)

The hindguts of many species of millipedes (Diplopoda) throughout the world are hosts to *Enterobryus* (Eccrinales) (Lichtwardt 1986, and unpublished), the first genus of Trichomycetes to be named (Leidy 1849a). Identifying or providing new names for species of *Enterobryus* may require large numbers of host specimens with different stages of development and much study, because of the intraspecific variability exhibited by most species of this genus (Lichtwardt 1986). We report here

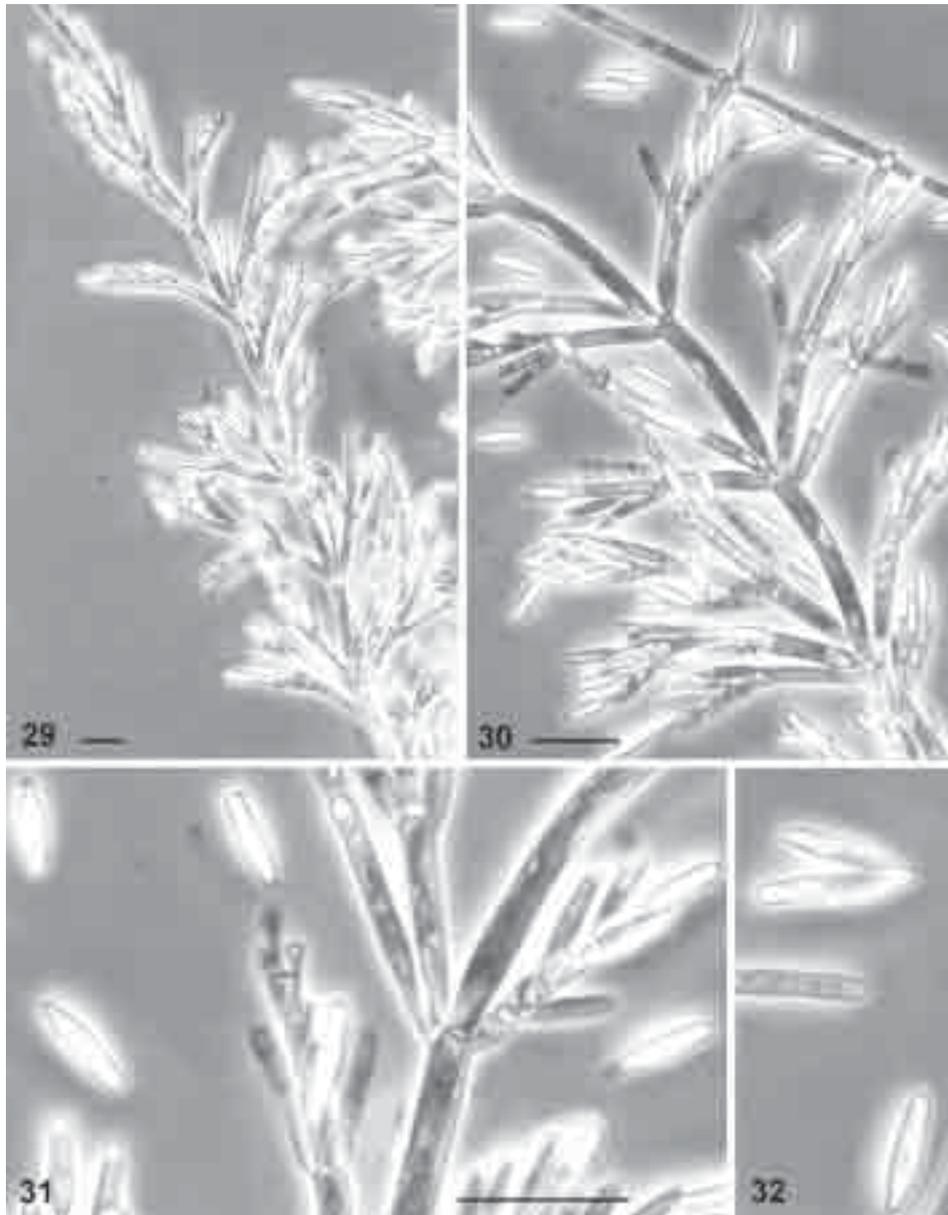

Figs 26–28: *Smittium aciculare* in the hindgut of a Simuliidae larva. Fig. 26: small, essentially unbranched, thallus with a tapered base (arrow). Fig. 27: released trichospore. Fig. 28: thallus with attached and detached trichospores. Scale bars = 25  $\mu\text{m}$

one species of *Enterobryus* that is probably new, which was found in a small spirobolid millipede on 16-X-2000 on the main Inpa campus (Site 6). The feature that makes this eccrinid unusual is the presence of extremely long holdfasts in mature thalli (Figs 33, 34). Holdfasts in Eccrinales attach thalli to the hindgut cuticle, and are extruded through pores in the wall at the base of the thalli (Mayfield & Lichtwardt 1980). In some species, such as this one, the holdfast substance may continue to be extruded during growth and maturation of the thallus. We did not find sufficient numbers of sporulating thalli to permit an adequate description of this *Enterobryus*.

*Harpella* sp.  
(Fig. 36)

In a larva of *Simulium perflavum* Roubaud (Simuliidae) collected 14-X-2000 from Igarapé do Km 4/ CIGS (Site 3) we found a species of *Harpella* that may be new, but it is not named at this time. It had very long thalli, up to 280-344  $\mu\text{m}$  with a rounded holdfast of less diameter than the thallus. Trichospores were curved to coiled, (46-)50(-60)  $\times$  3-6  $\mu\text{m}$ . About 12 trichospores per thallus were present. The length of the thalli and narrowness of the trichospores do not match any other described species.

Figs 29-32: axenic culture of *Smittium culisetae* isolated from a mosquito larva. Figs 29, 30: sporulating branches with a verticillate branching pattern. Fig. 31: attached and loose trichospores. Fig. 32: detached trichospores showing size variation that is typical of this species. Scale bars = 25  $\mu\text{m}$ ; for Fig. 32 see bar of Fig. 31

Figs 33-35: unbranched thalli of *Enterobryus* sp. (Eccrinales) growing in the hindgut of a millipede (Diplopoda), two showing extremely long secreted holdfasts and the tip of one thallus producing uninucleate sporangiospores. Scale bars = 25  $\mu$ m

*Stachylina* sp.  
(Figs 37, 38)

This undescribed species was attached to the peritrophic membrane of a *Corynoneura* sp. (Chironomidae: Orthocladiinae) larva collected 11-X-00 from Igarapé Canoas (Site 7). Sporulating thalli were about 110 x 5.5  $\mu$ m with one or two long-ellipsoidal trichospores measuring about 32 x 5  $\mu$ m. Specimens were too few to provide a good description of the species, but the dimensions of the trichospores and the few number produced per thallus suggest the species is new.

#### DISCUSSION

Simuliidae are hosts to seven genera of Harpellales, three of which we report here with new species: *G. tropicalis*, *H. amazonica*, and *S. brasiliense*. Another fungus from Simuliidae, *Simuliomyces microsporus*, has been found on four continents, including the countries of Costa Rica, Argentina and Chile (Lichtwardt 1986, 1997, Lichtwardt & Williams 1990, Lichtwardt & Arenas 1996, Lichtwardt et al. 1999a), but has not yet been recorded from Brazil. *Pennella* is a relatively common genus in Simuliidae in the US and Canada, but only two species have been found farther south, in Costa Rica: *P. simulii* M.C. Williams & Lichtw. and *P. montana* Lichtw. The latter species is also known to occur in Northwestern Argentina (Lichtwardt et al., 2000). Such distributions suggest that

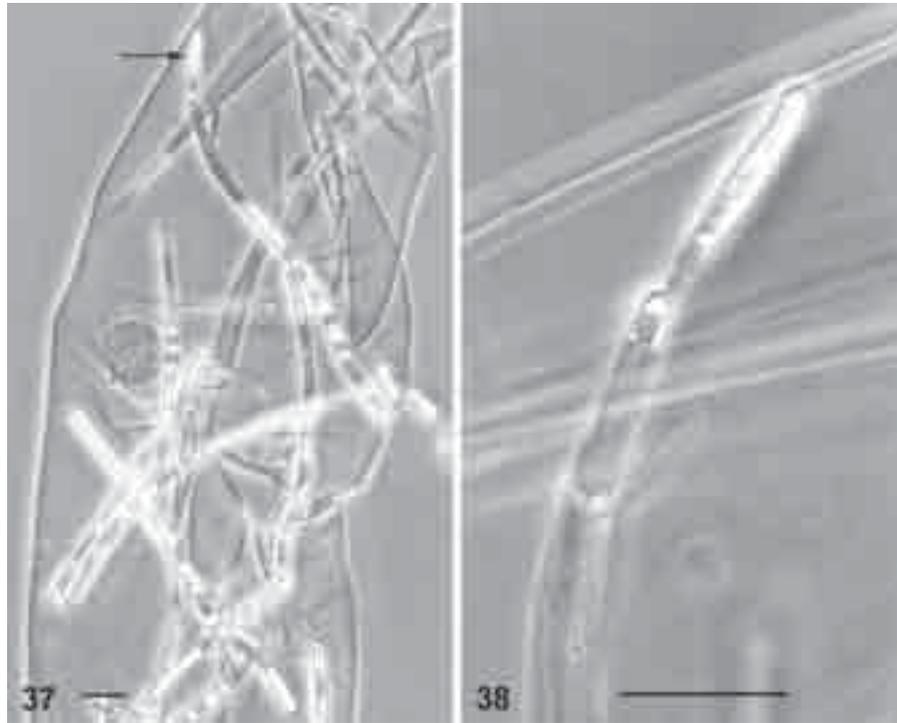

Fig. 36: a single thallus of *Harpella* sp., as seen within the peritrophic membrane of a Simuliidae larva, producing numerous curved trichospores at various stages of development (composite of two photomicrographs). Scale bar = 25  $\mu$ m

there are other genera and almost certainly new species of Trichomycetes living in Simuliidae that are yet to be discovered in Brazil.

Chironomidae are also frequent hosts of Harpellales, with six recorded genera inhabiting their guts. They are hosts to most known species of *Stachylina* (23 of 26) and *Smittium* (49 of 56), though six *Smittium* spp. are found in both Chironomidae and Simuliidae. In our studies we emphasized Trichomycetes in Simuliidae, and only described one new species in Chironomidae, *Stachylina paucispora*. Undoubtedly, the Amazon region contains numerous Chironomidae that will prove to be hosts to Harpellales when additional specimens are sought.

None of the new species in this paper have been found in Costa Rica, the only tropical region of the Americas where intensive studies on Harpellales have been done

Figs 37, 38: unbranched thalli of *Stachylina* sp. within the peritrophic membrane of a minute *Corynoneura* sp. (Chironomidae) larva; one thallus has produced a single trichospore (arrow). Scale bars = 25  $\mu$ m

(Lichtwardt 1994, 1997). *S. aciculare* from Amazonas appears to be the same species originally described from tropical Queensland, Australia. Such a disjunct distribution suggests that *S. aciculare* may exist in other regions of the world as well.

Of special interest is the biogeography of *Harpella*. *H. melusinae* is known from all areas of the Northern Hemisphere where Simuliidae have been collected and dissected, as well as in Australia and New Zealand, often occurring in a high percentage of larvae in almost all populations. Prior to the current study, investigation on Trichomycetes have been conducted in relatively few regions of the Americas, South of the US. With this in mind, it can be said that *H. melusinae* has not yet been found in Central or South America. Rather, *H. meridionalis* is the predominant and a very common species in Simuliidae in Southern Chile and Argentina (Lichtwardt & Arenas 1996, Lichtwardt et al. 1999a, 2000). *H. tica*, which generally appears to prefer Simuliidae larvae inhabiting warmer stream waters, was found in over 95% of Simuliidae larvae in Costa Rica (in streams as cool as 11-17.5°C but mostly 19.5-28°C) and subsequently was found in warm waters (17-24.5°C) in northwestern provinces of Argentina (Lichtwardt et al. 1999a) and Puerto Rico (22-25°C) (White et al. 2000). In the central Amazon region of Brazil, stream temperatures in the forest, tend to be constant, around 24°C throughout the year (Hamada & Adler 2001).

Factors that determine whether or not dipteran larvae are infected with particular species of Harpellales can be attributed to many aspects in their aquatic habitats, such

as temperature, organic matter, pH, and dissolved minerals, and undoubtedly also to historical biogeography and host specificity, but these ecological aspects that relate fungal symbionts to their hosts are just beginning to be addressed. A summary of tropical Trichomycetes recorded, in the literature has been provided by White et al. (2000).

#### ACKNOWLEDGMENTS

To the National Science Foundation PEET, grant DEB-9521811 and Inpa (PPI 1-3070) for partial support to R Lichtwardt. To Dr Claudio RF Vasconcelos and Dr José W Morais for the passalid and Diplopoda identifications, respectively; to MSc Arlindo Serpa Filho for the chironomid identifications and Jeferson Oliveira da Silva for technical support. To Dr Patricia M Eckel for translating the diagnoses into Latin. Dayse Queiróz made the map drawing.
